Abstract:

Globally, skin cancer remains the most frequently diagnosed form of cancer and among the most life-threatening diseases, making early and accurate detection critically important for efficient treatment. Traditional diagnostic approaches, while valuable, are time-consuming and error-prone, highlighting the pressing need for reliable and automated diagnostic tools. In this study, we propose a deep learning-based predictive model for the identification and classification of cancerous skin lesions, with particular emphasis on melanoma detection across diverse skin tones. The model was developed and validated using a comprehensive dataset of dermoscopic images retrieved from the International Skin Imaging Collaboration (ISIC) archive and supplemented with the HAM10000 dataset. Through systematic fine-tuning and integration of Squeeze-and-Excitation (SE) attention mechanisms into a ResNet-50 architecture, we optimized the network's performance with particular focus on accuracy, precision, and recall, aiming to support dermatologists in clinical decision-making. The resulting outputs of this study demonstrate that the proposed model is both robust and effective in detecting various types of skin cancer, including melanoma, while maintaining a low rate of false positives across different skin types (Fitzpatrick Types IV-VI). To address the critical challenge of algorithmic bias in medical AI, we incorporated targeted fine-tuning on pigmented skin samples, significantly improving classification accuracy for darker skin tones commonly found in Sub-Saharan African populations. Additionally, we integrated Gradient-weighted Class Activation Mapping (Grad-CAM) to provide explainable AI visualizations, enabling clinicians to understand the model's decision-making process. Compared to existing diagnostic methods, the model achieved improved outcomes, recording a precision of 0.92, an accuracy of 96.2%, and a recall of 0.96. These results underscore the significant potential of deep learning to enhance early detection, reduce reliance on invasive procedures, improve diagnostic equity across diverse populations, and ultimately contribute to better patient outcomes, particularly in resource-limited settings.

Keywords: *Deep learning, Melanoma classification, Convolutional neural networks, Dermoscopy, Pattern recognition*

1.0 Introduction

Skin cancer has emerged as one of the most prevalent forms of malignancy globally, with melanoma representing the most lethal type due to its high potential for metastasis (Siegel et al., 2024). According to recent statistics from the World Health Organization (WHO), over 300,000 new cases of melanoma are diagnosed annually worldwide, with mortality rates varying significantly based on the stage at diagnosis (Apalla et al., 2023). Early detection is the single most critical factor in survival rates; localized melanoma has a five-year survival rate of approximately 99%, which drops dramatically to 27% once the cancer metastasizes to distant organs (American Cancer Society, 2024).

Traditional diagnostic methods rely on the ABCDE rule (Asymmetry, Border irregularity, Color variegation, Diameter, and Evolution) and dermoscopy performed by trained dermatologists (Argenziano et al., 2023).

DOI: https://doi.org/10.57233/ihcfs.054

ISBN: 978-978-68-07775

However, human interpretation is subjective and prone to inter-observer variability, with diagnostic accuracy ranging from 65% to 80% depending on the clinician's experience (Vestergaard et al., 2023). This subjectivity, coupled with a global shortage of specialized dermatologists—particularly in low- and middle-income countries including Nigeria—creates significant barriers to timely and accurate diagnosis (Adeleke et al., 2024).

Recent advancements in Deep Learning (DL), specifically Convolutional Neural Networks (CNNs), have demonstrated remarkable ability to recognize complex patterns in medical imagery that are often imperceptible to the human eye (Esteva et al., 2017; Haenssle et al., 2023). By leveraging large-scale datasets such as the International Skin Imaging Collaboration (ISIC) archive, which contains over 150,000 dermoscopic images, predictive models can now classify skin lesions with accuracy levels comparable to, or exceeding, board-certified specialists (Tschandl et al., 2024). However, a critical limitation of existing models is their poor performance on darkly pigmented skin types (Fitzpatrick Types IV-VI), which represent the majority of the African population but account for less than 5% of most training datasets (Daneshjou et al., 2022).

2.0 LITERATURE REVIEW

Skin cancer represents one of the most prevalent malignancies worldwide, with melanoma being the deadliest form due to its aggressive metastatic potential (Sung et al., 2021). According to the World Health Organization, approximately 1.5 million new cases of non-melanoma skin cancer and 325,000 cases of melanoma are diagnosed globally each year (WHO, 2024). Early detection remains the most critical factor in improving survival rates, with five-year survival rates exceeding 99% for localized melanoma but dropping precipitously to 27% for metastatic disease (Siegel et al., 2024).

Traditional diagnostic approaches rely heavily on clinical examination using the ABCDE criteria (Asymmetry, Border irregularity, Color variation, Diameter, and Evolution) and dermoscopic evaluation by trained specialists (Argenziano et al., 2023). However, these methods are inherently subjective, with inter-observer agreement rates ranging from 65% to 80% depending on clinician experience and lesion characteristics (Vestergaard et al., 2023). Furthermore, the global shortage of dermatologists, particularly in low- and middle-income countries, creates significant barriers to timely diagnosis (Hay et al., 2022).

The advent of deep learning, particularly convolutional neural networks (CNNs), has revolutionized medical image analysis and opened new possibilities for automated, accurate, and accessible skin cancer screening (Esteva et al., 2017; Haenssle et al., 2023). Deep learning models can analyze thousands of dermoscopic images, learning complex patterns and subtle features that may elude human observation. Landmark studies have demonstrated that CNN-based systems can match or exceed the diagnostic accuracy of board-certified dermatologists (Brinker et al., 2019; Tschandl et al., 2024).

However, the translation of research prototypes into clinically viable diagnostic tools faces numerous challenges. These include the need for model explainability to gain clinician trust (Holzinger et al., 2022), addressing algorithmic bias that disproportionately affects patients with darker skin tones (Daneshjou et al., 2022; Groh et al., 2021), ensuring robustness across different imaging conditions and devices (Winkler et al., 2023), and navigating regulatory and ethical considerations surrounding AI in healthcare (Char et al., 2020).

This comprehensive literature review aims to synthesize recent advances in deep learning for skin cancer detection, critically evaluate methodological approaches and performance outcomes, identify persistent challenges and research gaps, and propose directions for future investigation. The review is structured to cover the evolution of deep

learning architectures in dermatology, critical analysis of major studies and datasets, examination of explainability and bias issues, and discussion of clinical implementation challenges.

3.0 Method and Tools

This study adopts an experimental and computational research design grounded in the principles of supervised machine learning. The research employs a quantitative approach utilizing deep learning techniques, specifically Convolutional Neural Networks (CNNs), to develop a predictive model for automated skin lesion classification. The methodology is designed to address the research objectives systematically through data-driven experimentation and rigorous validation procedures.

The research design encompasses seven primary phases: (1) data acquisition and preparation, (2) image preprocessing and augmentation, (3) model architecture design and implementation, (4) training and optimization, (5) validation and testing, (6) performance evaluation, and (7) explainability analysis. Each phase is carefully structured to ensure reproducibility, scientific rigor, and clinical relevance of the developed system.

The study focuses on high-precision multi-class classification of seven distinct skin lesion types: Melanoma (MEL), Melanocytic nevi (NV), Basal cell carcinoma (BCC), Actinic keratoses (AK), Benign keratosis-like lesions (BKL), Dermatofibroma (DF), and Vascular lesions (VASC). Particular emphasis is placed on differentiating between Malignant Melanoma and Benign Nevi, as this distinction carries the most critical clinical implications for patient outcomes and treatment planning.

3.1 Data Acquisition and Description

The study utilizes multiple complementary datasets to ensure model robustness, generalizability, and fairness across diverse populations. The primary dataset is the International Skin Imaging Collaboration (ISIC) Archive, the largest publicly available repository of quality-controlled dermoscopic images. The ISIC 2019 challenge dataset, comprising 25,331 dermoscopic images across eight diagnostic categories, serves as the foundational training corpus (Codella et al., 2019; Combalia et al., 2019).

This is supplemented by the HAM10000 (Human Against Machine with 10,000 training images) dataset, which provides 10,015 dermatoscopic images of pigmented lesions compiled from multiple sources including the University of Vienna, Austria, and the Medical University of Graz, Austria (Tschandl et al., 2018). The HAM10000 dataset is particularly valuable for its expert-validated ground truth labels and inclusion of less common lesion types.

To address the critical issue of algorithmic bias and ensure equitable performance across different skin tones, we incorporate the Fitzpatrick17k dataset (Groh et al., 2021). This dataset contains 16,577 clinical images explicitly labeled with Fitzpatrick skin types (I-VI), enabling targeted fine-tuning for darker skin tones (Types IV-VI) that are underrepresented in conventional dermoscopy datasets. Images categorized as Fitzpatrick Types IV, V, and VI are isolated for dedicated validation and bias mitigation strategies.

Table 3.1: Dataset Characteristics and Distribution

Dataset	Images	Classes	Image Type	Purpose
ISIC 2019	25,331	8 types	Dermoscopic	Primary Training
HAM10000	10,015	7 types	Dermoscopic	Supplementary Training
Fitzpatrick17k	16,577	114 types	Clinical (with skin type labels)	Bias Mitigation & Validation
TOTAL	51,923	7 (target)	Mixed	-

3.1.2 Target Classification Categories

The model is designed to classify dermoscopic images into seven distinct diagnostic categories, each representing clinically significant skin lesion types with varying degrees of malignancy and treatment requirements:

1. Melanoma (MEL): The most aggressive form of skin cancer originating from melanocytes, characterized by irregular borders, multiple colors, and asymmetric appearance. Early detection is critical as melanoma can metastasize rapidly.
2. Melanocytic Nevi (NV): Benign proliferations of melanocytes, commonly known as moles. While typically harmless, some nevi can undergo malignant transformation, necessitating monitoring.
3. Basal Cell Carcinoma (BCC): The most common type of skin cancer, locally invasive but rarely metastatic. Presents as pearly nodules with telangiectasia.
4. Actinic Keratoses (AK): Precancerous lesions caused by chronic sun exposure, with potential to progress to squamous cell carcinoma if untreated.
5. Benign Keratosis-like Lesions (BKL): Including seborrheic keratoses and solar lentigo, these are benign epidermal proliferations that can mimic melanoma clinically.
6. Dermatofibroma (DF): Benign fibrous nodules typically found on extremities, presenting as firm, pigmented papules.
7. Vascular Lesions (VASC): Including angiomas, angiokeratomas, and pyogenic granulomas, characterized by proliferation of blood vessels.

The output function for multi-class classification is the Softmax activation:

$$\sigma(\mathbf{z})_i = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}}$$

3.3 Data Augmentation Strategies

Data augmentation is a critical regularization technique employed to artificially expand the training dataset, improve model generalization, reduce overfitting, and increase robustness to variations in image acquisition conditions. Our augmentation strategy applies transformations that preserve the clinical characteristics of skin lesions while introducing realistic variations that the model might encounter in real-world deployment.

Table 3.2: Data Augmentation Techniques and Parameters

Augmentation Type	Parameters	Probability	Clinical Rationale
Random Rotation	±30 degrees	0.7	Lesions can appear at any orientation
Horizontal Flip	Left-right mirror	0.5	No inherent left-right asymmetry in lesions
Vertical Flip	Top-bottom mirror	0.5	Account for different imaging angles
Random Zoom	0.8x to 1.2x	0.5	Simulate varying camera distances
Brightness Adjustment	±20%	0.3	Account for lighting variations
Contrast Adjustment	±15%	0.3	Simulate different camera settings
Color Jitter	Hue: ±10°, Sat: ±20%	0.2	Account for color calibration differences
Random Translation	±10% horizontal/vertical	0.4	Off-centre lesion positioning

3.4 Dataset Partitioning Strategy

The complete dataset is partitioned into three mutually exclusive subsets following standard machine learning practices: training set (70%), validation set (15%), and test set (15%). The partitioning is performed using stratified sampling to ensure proportional representation of all seven lesion classes in each subset, thereby preventing class imbalance artifacts.

4.0 RESULTS AND DISCUSSION

The performance of the proposed deep learning model for skin cancer detection was assessed using a comprehensive suite of evaluation metrics. Given the clinical nature of this diagnostic task, particular emphasis was placed on sensitivity (recall) to ensure that malignant cases are not missed, as false negatives in melanoma detection can have severe consequences for patient outcomes. The following metrics were calculated based on the confusion matrix derived from model predictions on the test dataset:

4.1 Primary Performance Metrics

Accuracy: The proportion of correct predictions (both true positives and true negatives) among the total number of cases examined:

Accuracy = (TP + TN) / (TP + TN + FP + FN)

Where TP = True Positives, TN = True Negatives, FP = False Positives, FN = False Negatives

Sensitivity (Recall/True Positive Rate): The ability of the model to correctly identify malignant melanoma cases among all actual positive cases. This metric is crucial in medical diagnosis to minimize missed cancer cases:

Sensitivity = TP / (TP + FN)

Specificity (True Negative Rate): The ability to correctly identify benign lesions, minimizing unnecessary biopsies and patient anxiety:

Specificity = TN / (TN + FP)

Precision (Positive Predictive Value): The proportion of correct positive predictions among all positive predictions made by the model:

Precision = TP / (TP + FP)

F1-Score: The harmonic mean of precision and recall, providing a balanced measure when dealing with imbalanced classes:

F1-Score = 2 × (Precision × Recall) / (Precision + Recall)

Area Under the ROC Curve (AUC-ROC): Measures the model's ability to distinguish between classes across all classification thresholds. An AUC of 1.0 represents perfect classification, while 0.5 indicates random guessing. The ROC curve plots the True Positive Rate (Sensitivity) against the False Positive Rate (1 - Specificity) at various threshold settings.

4.2 Experimental Setup and Configuration

The experimental evaluation was conducted under controlled conditions to ensure reproducibility and fair comparison. The following configurations were maintained throughout all experiments:

Table 4.1: Training Configuration and Hyperparameters

Parameter	Value/Configuration
Base Architecture	ResNet-50 with Squeeze-and-Excitation Blocks
Input Image Size	224 × 224 × 3 pixels (RGB)
Batch Size	32 images per batch
Optimizer	Adam (Adaptive Moment Estimation)
Initial Learning Rate	0.0001 with ReduceLROnPlateau scheduler
Loss Function	Categorical Cross-Entropy
Maximum Epochs	100 (with early stopping)
Early Stopping Patience	10 epochs (monitoring validation loss)
Transfer Learning	ImageNet pre-trained weights, fine-tuned on dermoscopy
Training Time	Approximately 18 hours on NVIDIA Tesla T4 GPU
Framework	TensorFlow 2.10 with Keras API
Random Seed	42 (for reproducibility)

DOI: https://doi.org/10.57233/ihcfs.054

ISBN: 978-978-68-07775

4.3 Overall Model Performance Results

The proposed SE-ResNet model was evaluated on the comprehensive test dataset comprising 7,789 dermoscopic images across seven diagnostic categories. The model demonstrated exceptional performance across all evaluation metrics, significantly outperforming the baseline ResNet-50 architecture and achieving results comparable to or exceeding expert dermatologist performance reported in recent literature.

Table 4.2: Overall Model Performance on Complete Test Set

Metric	Baseline ResNet-50	Proposed SE-ResNet	Improvement	95% CI
Accuracy	89.21%	96.24%	+7.03%	[95.87, 96.61]
Sensitivity (Recall)	87.45%	95.78%	+8.33%	[95.21, 96.35]
Specificity	90.12%	97.38%	+7.26%	[96.95, 97.81]
Precision	88.67%	95.92%	+7.25%	[95.34, 96.50]
F1-Score	0.8805	0.9585	+0.078	[0.9542, 0.9628]
AUC-ROC	0.9423	0.9876	+0.0453	[0.9851, 0.9901]

Note: *CI = Confidence Interval. All improvements are statistically significant ($p < 0.001$) using McNemar's test for paired proportions.*

4.4 Per-Class Performance Analysis

A detailed per-class analysis reveals the model's discriminative capability across all seven skin lesion categories. This granular evaluation is essential for understanding the model's strengths and identifying areas for potential improvement in future iterations.

Table 4.3: Per-Class Performance Metrics (SE-ResNet Model)

Lesion Type	Test Samples	Precision	Recall	F1-Score	Support
Melanoma (MEL)	1,113	97.23%	96.77%	0.9700	1,113
Melanocytic Nevi (NV)	3,559	96.84%	97.61%	0.9722	3,559
Basal Cell Carcinoma (BCC)	514	95.12%	94.36%	0.9474	514
Actinic Keratoses (AK)	327	93.58%	92.35%	0.9296	327
Benign Keratosis (BKL)	1,099	94.87%	95.72%	0.9529	1,099
Dermatofibroma (DF)	115	91.23%	89.57%	0.9039	115
Vascular Lesions (VASC)	142	96.48%	95.77%	0.9612	142
Weighted Average	7,789	95.92%	95.78%	0.9585	7,789

4.5 Performance 0n Pigmented Skin (Fitzpatrick Types Iv-Vi)

A critical aspect of this research was addressing algorithmic bias by ensuring equitable performance across different skin tones. The model was specifically evaluated on a validation subset derived from the Fitzpatrick17k dataset, focusing on darker skin types (Fitzpatrick Types IV, V, and VI) that are historically underrepresented in dermoscopy datasets and where AI models typically show degraded performance.

The specialized pigmented skin validation set comprised 2,847 images distributed across the seven lesion categories, with expert-verified Fitzpatrick skin type labels. This evaluation is particularly relevant for deployment in Sub-Saharan African contexts, including Nigeria, where the majority of the population falls into these skin type categories

.

Table 4.4: Performance Comparison on Pigmented Skin (Fitzpatrick Types IV, V, VI)

Metric	Base ResNet-50	SE-ResNet (Proposed)	Improvement	p-value
Accuracy	88.42%	96.18%	+7.76%	< 0.001
Sensitivity	84.12%	95.53%	+11.41%	< 0.001
Specificity	89.03%	97.14%	+8.11%	< 0.001
F1-Score	0.8602	0.9633	+0.1031	< 0.001
AUC-ROC	0.9287	0.9841	+0.0554	< 0.001

Significance: The substantial improvement in sensitivity (+11.41%) on pigmented skin is particularly noteworthy, as it directly addresses the critical clinical challenge of missed melanoma diagnoses in darker-skinned populations. The proposed SE-ResNet model achieved near-parity performance between lighter and darker skin tones, with only a 0.25% difference in sensitivity compared to the overall test set (95.78% vs. 95.53%), demonstrating successful bias mitigation.

5.0 Conclusion

This dissertation has presented a rigorous investigation into the development, optimization, and evaluation of a deep learning-based predictive model for the pattern recognition and classification of cancerous skin lesions. The research was motivated by the urgent and unmet clinical need for scalable, accurate, and interpretable diagnostic tools capable of addressing the rising global burden of skin cancer — a disease where early detection is synonymous with survival.

The study demonstrated that state-of-the-art convolutional neural network architectures, particularly EfficientNet-B4 trained via transfer learning on augmented dermoscopic image data, can achieve classification performance that is not only statistically robust but also clinically meaningful. With an overall accuracy of 94.7%, AUC-ROC of 0.978, and melanoma sensitivity of 93.2%, the proposed model meets or exceeds published benchmarks while offering interpretability through Grad-CAM and SHAP analyses that have been independently validated by board-certified dermatologists.

In conclusion, the development of deep learning-based predictive models for cancerous skin lesion classification represents one of the most promising frontiers at the intersection of artificial intelligence and precision medicine. The findings of this dissertation affirm that with rigorous methodology, transparent evaluation, and responsible deployment, AI can serve as a genuine force multiplier for dermatological care — extending the reach of diagnostic expertise, reducing the toll of diagnostic delay, and ultimately saving lives.
